**Abstract**

Automotive safety has been a critical focus for both national and international research institutions in recent years. The combined control of lateral dynamics and roll stability in vehicles has been extensively studied, often relying on automotive models to design and tune controllers. However, these models frequently include parametric uncertainties, nonlinear dynamics, and simplifying assumptions, which can lead to suboptimal controller performance in real-world applications. This work proposes a unified chassis controller (UCC) to regulate lateral and roll dynamics during abrupt maneuvers, comparing two control strategies: one based on traditional PID controllers and another based on model-free controllers (MFC). Both approaches employ three independent controllers to maintain the side-slip angle, yaw rate, and roll angle within safe limits. The robustness and performance of these control structures is evaluated using a Sine With Dwell maneuver in a co-simulation environment combining MATLAB/Simulink® and CarSim®. Results demonstrate that while the PID-based UCC struggles to maintain stability under varying road conditions, the MFC-based UCC achieves superior robustness and performance, effectively regulating the state variables across different scenarios. These findings highlight the robustness and adaptability of MFCs, making them a promising solution for enhancing vehicle safety.

**Keywords:** UCC, robustness, CarSim, MFC

## 1 Introduction

Millions of people are affected by car accidents annually. According to the UN, 1.3 million people die and around 50 million suffer severe injuries each year (Naciones Unidas (Noticias ONU), 2022). In the U.S. alone, traffic accidents caused approximately 2.1 million emergency visits and 40,000 deaths in 2020, with an estimated cost of $430 billion due to healthcare and reduced life expectancy (Ahmed et al., 2023).

In response to the global rise in accidents, the UN adopted Resolution A/RES/74/299 in 2020, urging countries to strengthen road safety policies and adopt the Decade of Action for Road Safety 2021–2030. The resolution emphasizes

improved road safety management, safer vehicles and infrastructure, and public awareness to reduce traffic fatalities by 50% (World Health Organization, 2021).

Accidents often result from loss of control due to sudden maneuvers, tire failures, or driver inattention (Friedman et al., 2010). Such situations manifest as increases in side slip angle and yaw rate. Excessive side slip angle raises rollover risk, especially when weight shifts laterally (Stolle et al., 2011), while high yaw rates may exceed tire grip limits, causing oversteer and loss of control (Zhan, 2017). The vehicle roll angle depends on vehicle speed, steering, and geometry, and its increase reduces vertical load on wheels, heightening rollover risk (Nguyen, 2023). The roll rate measures how quickly the vehicle leans in a turn and is influenced by weight distribution, suspension, and tire grip. Sudden direction changes can sharply increase roll rate, leading to loss of control (Friedman et al., 2010).

Electronic Stability Control (ESC) is the most widespread system to counteract lateral instability. ESC maintains stability by selectively braking wheels and reducing engine power (Aleksander and Edward, 2007), and may involve steering control systems (Li et al., 2023). To control roll angle and rate, systems like active or semi-active suspensions (Jin et al., 2023; Ding et al., 2023) and anti-roll bars (Anafjeh et al., 2023) are commonly used, improving both stability and passenger comfort. Unified Chassis Control (UCC) enhances vehicle robustness and performance by coordinating multiple subsystems to improve stability and comfort. It helps mitigate understeer/oversteer, reduces body roll, improves traction, and is applicable to electric and hybrid vehicles. UCC has proven effective in preventing rollovers by detecting and correcting critical situations such as high speed and sudden maneuvers (Wanki et al., 2012).

This work proposes a model-free control (MFC) approach to UCC. MFC is advantageous in that it does not rely on precise system models. Section 1.1 presents the model structure, that is, without the parameters precisely known, followed by a literature review on UCC and MFC. Section 2 outlines the mathematical principles of MFC and deduces formulas for the ultra-local controllers, that are based in PID controllers (here called intelligent PIDs, or iPIDs). Section 3 details the proposed UCC architecture. Section 4 addresses MFC controller tuning, based in Matlab® and Carsim® simulations. Section 5 describes the validation tests to be performed, and Section 6 discusses the results. In particular, the UCC with MFC controllers (the iPIDs) are the only controllers capable of guaranteeing robustness of stability during the tests (the open-loop and simple PID controllers unstabilize after some time). Finally, section 7 concludes the study.

## 1.1 UCC model-based

Currently, most of the UCC systems use vehicle models to obtain and adjust the parameters of the individual controllers.

A widely adopted approach is the bicycle model, illustrated in Fig. 1. In this representation, $F_f$ and $F_r$ denote the lateral forces acting on the front and rear axles, respectively; $V_{ref}$ is the vehicle's velocity vector; and $\alpha_f$ and $\alpha_r$ are the slip angles of the front and rear wheels. The Center of Gravity (CG) is located at distances $l_f$ and $l_r$ from the front and rear axles. The side-slip angle, $\beta$, represents the relationship between the vehicle's longitudinal and lateral velocities, while $r = \dot{\psi}$ denotes the yaw rate. Additionally, $\delta_f$ epresents the front wheel steering angle, and $V_f$ and $V_r$ are the velocity vectors at the front and rear tires.

This model is frequently integrated into Model Predictive Control (MPC) frameworks, as seen in Ahmadi (2021), Gidlewski et al. (2017), and Yakub et al. (2016). Other studies, such as Owen (2018), utilize it to analyze the impact of the center-of-mass location on vehicle performance, while Bilen (2010) and Fahimi (2013) employ it for computational simulations and controller design (Xia et al., 2021).

To achieve higher fidelity, some authors develop more complex models to capture intricate vehicle dynamics and subsystem interactions. For instance, Lai and Jiang (2021) introduced an 18-degree-of-freedom (DOF) model to represent comprehensive chassis dynamics. This model facilitates the design of a UCC system that evaluates the trade-off between ride comfort and handling stability across various maneuvers, accounting for the complex coupling between subsystems. The 18-DOF model treats the vehicle as five rigid bodies: a sprung mass (chassis)

**Fig. 1**: Bicycle model

with 6-DOF (roll, pitch, yaw, and translational motions) and four unsprung masses (wheels). Each wheel is modeled with 3-DOF, corresponding to vertical displacement, wheel rotation, and steering rotation.

Similarly, Chen et al. (2021) proposed a 6-DOF rigid-body model that integrates planar motion (longitudinal, lateral, and yaw) with spatial motion (vertical, roll, and pitch). Combined with unsprung mass dynamics, this approach treats the vehicle as a unified system under longitudinal and lateral accelerations. To characterize nonlinear tire behavior, the authors utilize Pacejka's Magic Formula, an empirical approach that unifies longitudinal force, lateral force, and self-aligning moment through parameter sets fitted to experimental data.

In summary, the use of model-based controls in vehicle dynamics offers the fundamental advantage of enabling precise and coordinated management of complex multivariable systems—such as the interaction between independent wheel drive and active suspension—facilitating the incorporation of physical constraints and the prediction of critical states to maximize safety and comfort Li et al. (2022). However, this approach has critical drawbacks, primarily a high demand for computational resources to process high-fidelity models in real time Guo et al. (2020), as well as significant sensitivity to modeling errors (model mismatch) Lew et al. (2024). Any discrepancy between mathematical parameters and real-world conditions—such as variations in mass or unexpected changes in tire friction—can significantly degrade system performance and stability if robust adaptation mechanisms are not in place.

## 1.2 Uncertainty Compensation

One of the most widely used schemes for validating controller design in automotive systems is the CarSim® software. CarSim® mathematical models are highly optimized for computational efficiency and are represented at the system level, meaning that vehicle data is intended to be measured or calculated and does not rely on detailed knowledge of component materials or suspension linkage complexities. When using a CarSim® model, major issues may include the need for detailed vehicle data, accurate environmental conditions, and a good understanding of vehicle models at the system level. Users should also be aware of the importance of accurate kinematics and suspension compliance, tire strength and moment properties, and environmental conditions, as well as the potential impact of limited reference data on the accuracy of simulation results (Mechanical Simulation Corporation, 2021).

Due to the above, the study of MFC for the regulation of vehicle dynamics in real-time is of interest. It should be noted that the term "Model-free control" can be seen in the literature as referring to a wide range of controllers that can go from "classical" proportional-integral-derivative (PID) to robust and adaptive control techniques derived, for example, from neural networks, fuzzy systems, and soft computing. The type of MFC used in this paper (intelligent PID based on ultra-local model) was presented by Fliess and Join (2008), which makes it a novel technique and alternative to classical control in the automotive domain. Several authors have used this control technique as part of an automotive UCC system. In general, the MFC can be used in this field to regulate the longitudinal dynamics (direction and/or speed) of the vehicle (Dong et al., 2014), as a controller of the lateral dynamics (yaw rate and/or side slip angle) as in the case of Radac and Precup (2018), for the control of the joint lateral and longitudinal dynamics like in Menhour et al. (2018) and Rizk et al. (2023), or for the control of the vertical dynamics, that is roll, roll rate and/or pitch (Mustafa et al., 2019).

However, there are no references in the literature to works that use this control method to jointly regulate the lateral and vertical dynamics at the same time and in a single UCC system. In

the present work, an automotive UCC system is designed using only MFC controllers to minimize the side-slip angle, reducing the yaw rate error and maintaining the vertical stability corresponding to the car roll angle and roll rate. The proposed system is tuned and validated through a Sine With Dwell maneuver in CarSim® software. Those are original contributions, to the best of the authors' knowledge.

# 2 The ultra-local model-based MFC controller

The Model-Free Controller (MFC) based ultra-local model assumes that the system response will behave as shown in Eq. (1) for a small time window:

$$y^v = F + \alpha u, \tag{1}$$

where $y^v$ represents the $v$th derivative of the output (usually $v = 1$ or $v = 2$) (Fliess, 2009), and $F$ is the input/output ratio of a simplified and little-known model of the plant. This parameter is a piecewise constant function that is updated in each time window and also includes measured and unmeasured perturbations of the plant. On the other hand, $\alpha \in \mathbb{R}$ is a number that represents a non-physical constant parameter. This parameter is defined by the designer in such a way as to have the same order of magnitude as the unknown real parameter, and then an adjustment is made based on the system's time response. In this paper, there are three plant variables: yaw rate ($\dot{\psi}$), side-slip angle ($\beta$), and roll angle ($\phi$), where the last two ones are controlled using a second-order ultra-local model, while the first one is represented by a first-order ultra-local model.

Assuming that the model represents the plant dynamics in a short time window, then the stabilizing intelligent PID control (iPID) can be computed by:

$$u = \frac{-F}{\alpha} + \frac{\ddot{y}^*}{\alpha} + K_P e + K_I \int e\, dt + K_D \frac{de}{dt}, \tag{2}$$

where $\ddot{y}^*$ is the reference second time-derivative that the output is intended to follow, $e = y - y^*$ is the system tracking error and $K_P$, $K_I$ and $K_D$ are the gains of a conventional PID controller. These gains are adjusted to cancel out the measured output and impose the desired dynamics. It should be noted that this control can be in the form of a PI or a PD as appropriate. Finally, the control method involves estimating the value of $F$ in constant time windows. It can be demonstrated that even if the initial guess for $\alpha$ is incorrect, the estimator will correctly estimate the compensation of $F$ (Pereira das Neves and Augusto Angélico, 2022). Therefore, $\alpha$ will only slightly affect the performance but will ensure the system stability.

## 2.1 $F$ estimator to the ultra-local model of $\beta$ and $\phi$

As mentioned earlier, the ultra-local models of $\beta$ and $\phi$ are considered of second order ($v = 2$). In that case, the equation would be $\ddot{y} = F_2 + \alpha u$. Applying the Laplace transform in this equation results in $s^2Y(s) - sy(0) - \dot{y}(0) = F_2/s + \alpha U(s)$. Then, by taking the derivative of the equation concerning $s$ twice, one obtains:

$$2Y(s) + 4s\frac{d}{ds}Y(s) + s^2\frac{d^2}{ds^2}Y(s) = \\ = 2s^{-3}F_2 + \alpha\frac{d^2}{ds^2}U(s). \tag{3}$$

Finally, multiplying Eq. (3) by $\frac{1}{s^3}$ results in[1]:

$$2\frac{1}{s^3}Y(s) + 4\frac{1}{s^2}\frac{d}{ds}Y(s) + \frac{1}{s}\frac{d^2}{ds^2}Y(s) = \\ = 2F_2\frac{1}{s^6} + \alpha\frac{1}{s^3}\frac{d^2}{ds^2}U(s). \tag{4}$$

Returning to the time domain using the Laplace anti-transform, it is obtained:

$$F_2 = \frac{60}{t^5}\int_0^t (t^2 - 6t\tau + 6\tau^2)y(\tau)\, d\tau + \\ - \frac{30\alpha}{t^5}\int_0^t (t-\tau)^2\tau^2 u(\tau)\, d\tau. \tag{5}$$

## 2.2 $F$ estimator to the ultra-local model of $\dot{\psi}$

The ultra-local model of $\dot{\psi}$ is considered of first order ($v = 1$). In that case, the equation would

[1] This process ensures that integral terms appear in every factor, thereby aiding in noise reduction.

look like $\dot{y} = F_1 + \alpha u$. The demonstration is very similar to the estimator of second order. Applying the Laplace transform in this equation results in $sY(s) - y(0) = F_1/s + \alpha U(s)$. Then, by taking the derivative of the equation by $s$, one has:

$$Y(s) + s\frac{d}{ds}Y(s) = -s^{-2}F_1 + \alpha\frac{d}{ds}U(s). \quad (6)$$

Finally, multiplying the Eq. (6) by $\frac{1}{s^2}$ results in:

$$\frac{Y(s)}{s^2} + \frac{1}{s}\frac{d}{ds}Y(s) = -F_1 + \frac{\alpha}{s^2}\frac{d}{ds}U(s). \quad (7)$$

Upon returning to the time domain via the Laplace inverse transform, one obtains:

$$F_1 = -\frac{6}{t^3}\int_0^t (t - 2t\tau)y(\tau)\,d\tau + \\ -\frac{6\alpha}{t^3}\int_0^t (t-\tau)\tau u(\tau)\,d\tau. \quad (8)$$

### 2.3 Discretization of algebraic estimators

The computational application of the estimator is possible through the window integral approximation. For this, the size of the integration window ($T$) must be decided, where, in general, the larger the window, the more precise the estimated value will be. On the other hand, the control will be slower since the estimator will take longer to converge to the value. Considering the response speed of the car dynamics, the windows for all estimators were defined as $T = 1.0$ s.

Considering the trapezoidal approximation of the integral, the estimators (of first and second order) can be written as:

$$\hat{F}_2 = \frac{60}{T^5}\sum_{k=0}^{T/T_s} a_k(T^2 - 6TkT_s + 6(kT_s)^2)y[k] + \\ -\frac{30\hat{\alpha}}{T^5}\sum_{k=0}^{T/T_s} a_k(T - kT_s)^2(kT_s)^2 u[k], \quad (9)$$

and

$$\hat{F}_1 = -\frac{6}{T^3}\sum_{k=0}^{T/T_s} a_k(T - 2TkT_s)y[k] + \\ -\frac{6\hat{\alpha}}{T^3}\sum_{k=0}^{T/T_s} a_k(T - kT_s)kT_s u[k], \quad (10)$$

where:

$$a_k = \begin{cases} T_2/2, & k = 0 \text{ and } k = T/T_s \\ T_s, & k = 1, \ldots, T/T_s - 1 \end{cases}. \quad (11)$$

## 3 UCC structure

In this work, an upstream architecture with multi-layer Coordination (MuC) is proposed for vehicle control. Fig. 2 shows the architecture with its components. In this architecture, inputs such as the longitudinal speed, steering angle of the front wheels and the system states (lateral speed $V_y$, yaw rate $\dot{\psi}$, roll angle $\phi$ and roll rate $\dot{\phi}$) are obtained from CarSim® as it were from a real car.

**Fig. 2**: UCC architecture

### 3.1 Supervision layer

The supervision layer aims to compute the references, as well as conditions under which the controller will act. The reference for $\beta$ is zero and it is calculated based on the estimated car lateral speed, as shown in Eq. (12). It is also defined that the controller for $\beta$ only performs whether it is outside the limits in Eq. (13). In the case of the yaw rate, the controller's reference is calculated based in the longitudinal speed, the steering angle of the front wheels, and the coefficient of ground friction. The controller's operating range is determined by the limits described in Eq. (14). In

the case of the roll angle, the reference will always be zero, as one of the controller's objectives is to reduce this parameter. The equations are:

$$\beta = \tan^{-1}(\frac{V_y}{V_x}), \tag{12}$$

$$\beta \leq \beta_{lim} = \pm 2^\circ, \tag{13}$$

$$\dot{\psi}_D = \min\left(\left|\frac{\mu g}{V_x}\right|, \left|G_{\dot{\psi}}\delta_f\right|\right) \cdot \text{sign}(\delta_f), \tag{14}$$

where, $G_{\dot{\psi}} = V_x/(L + K_{us}V_x^2)$, $V_x$ is the car longitudinal speed, $L$ is the distance between the car's axles in meters and $K_{us}$ is the under-steer coefficient.

### 3.2 High level controller

The high-level controller design uses the references calculated by the supervision layer and the estimated states and calculates the torques needed to control the dynamics. In the case of lateral dynamics (which involves $\dot{\psi}$ and $\beta$), the control signal will be a torque around the car's z-axis ($M_z$). This signal is setting a saturation level of $\pm$8000Nm. To control the roll angle, torque is calculated around the x-axis ($M_x$). This signal is limited by saturation levels of $\pm$1500Nm. Fig. 3 shows the implementation of this controller in Matlab/Simulink®.

### 3.3 Coordination layer

As can be seen in Fig. 3, in the coordination phase, a Pure Subsumption strategy is used to weigh up which of the control signals corresponding to $\beta$ and $\dot{\psi}$ will have more weight in the final torque calculation. This layer is not involved in controlling the roll angle.

### 3.4 Control allocation

At this step, the control signals calculated in the previous steps are transformed into "understandable" variables by the subsystems that act directly on the car's chassis. In the case of the torque on the z-axis, it will be transformed into individual brake pressure signals for each wheel by the ABS. In the case of $M_x$, it will be transformed into suspension forces relating to the active stabilizer bar (AARB) system. This step is carried out directly by the CarSim® software.

### 3.5 Individual actuators

The individual brake pressure signals and the motor torque signal of the AARB system from the previous step are taken in this step as references for the controllers of the car's ABS and the active stabilizer bar system, respectively. The control of these systems finally makes it possible to establish the desired behavior of the controlled dynamics. Like the previous one, this stage is implemented by CarSim® software.

## 4 Control tuning

In the following subsections, a demonstration of how to adjust the parameters $\alpha$, $K_P$, and $K_D$ of the iPD proposed controllers is performed (in this paper, we consider the integrative factor equals to zero). It should be noted that this tuning is empirically done and that the dynamics to be controlled do not require high precision in tracking the corresponding references for the system to exhibit proper behavior.

### 4.1 $\alpha$ adjustment

This parameter is set individually for each control law, and has direct influence on the system outputs ($M_z$ and $M_x$ torques). Since the $M_z$ signal is composed of the sum of individual signals corresponding to the side-slip angle control and the yaw rate control, it is necessary to adjust simultaneously $\alpha_\beta$ and $\alpha_{\dot{\psi}}$. A bad choice of these parameters can result in an oscillatory control signal with a high saturation time and/or an unsatisfactory maneuver performance. In this work, the values of $\alpha_s$ are empirically obtained looking for a relationship between them and the time response of the controlled parameters. Higher $\alpha$ value can induce some delay in the system response while a lower $\alpha$ generates a more oscillatory control signal. The objective then is to find a equilibrium $\alpha$. The selected $\alpha$ values are $\alpha_\beta = 0.01$, $\alpha_{\dot{\psi}} = 10^{-3}$ and $\alpha_\phi = 10^{-2}$.

### 4.2 iPD adjustment

It was verified by simulations that the variation of the $K_d$ parameter does not have influence on the system response. The $K_p$ was adjusted firstly for the yaw rate and side-slip angle controllers and then for the roll control. The adjustment must

**Fig. 3**: UCC implementation

keep a balance between reducing the steady state error and producing an oscillatory control signal. It should be noted that in the event of a sudden maneuver (as in the case of SWD) the control must prioritize the safety over the comfort. This is evidenced by the increase in the roll rate signal. Finally, the iPD adjustment is as follows: $Kp_\beta = 20$; $Kd_\beta = 3$; $Kp_{\dot{\psi}} = 50$; $Kd_{\dot{\psi}} = 3$; $Kp_\phi = 200$; $Kd_\phi = 3$.

# 5 Experiment design

To validate the designed UCC, it is simulated in Matlab/Simulink® acting on the Carsim® SUV model adapted to the parameters referred in Arronte et al. (2023) in a Sine With Dwell (SWD) maneuver. This simulation will be compared to the response of the traditional PID controllers designed in Arronte et al. (2023) acting under the same conditions. To show the system's robustness, tests are performed three different $\mu$ values (Ahrenhold et al., 2023): $\mu = 0.7$ (Dry Asphalt Road), which simulates good grip and stability for vehicles, $\mu = 0.5$ (Wet Road), which corresponds to reduced traction due to a lubricating film of water, increasing the risk of skidding, and $\mu = 0.3$ (Icy Road), which simulates extremely low traction, and requires careful driving and often needs specialized tires or chains for safety.

The SWD maneuver involves accelerating the vehicle to a speed of just over 80 km/h without steering or braking, leaving it in the highest gear up to 80 km/h, and then using a robot to apply

**Fig. 4**: Steering Angle for the Sine With Dwell maneuver

a steering control in the form of a sine wave with a dwell (momentary pause in the maximum steering angle). The purpose of the test is to evaluate the vehicle's response to a sudden evasive maneuver, such as swerving to avoid an obstacle, and to ensure compliance with regulations such as USA FMVSS 126 and UN/ECE Regulation No. 13-H Mechanical Simulation Corporation (2012). The system simulation is performed by using CarSim® and Matlab® together. Figure 4 shows the waveform of the steering signal in this maneuver.

# 6 Simulation results

The UCC is tested by simulating a SWD maneuver as specified above for three different values of friction coefficient as described. The tests are performed for open-loop situation (without

controller), PID controllers as designed in Arronte et al. (2023), and iPD MFC controllers. It is shown that for the first and second cases, stability is not even guaranteed.

## 6.1 Simulation for $\mu = 0.7$

Figures 5a and 5b show the side slip angle and yaw rate in the SWD maneuver for $\mu = 0.7$. Here, both the controllers, that is PID and iPD (MFC), manage to decrease the side slip angle during the maneuver. Also, the measured yaw rate follows the reference for both controllers. It can be observed that the vehicle fails to complete the maneuver without the action of any controller (open-loop). Figures 5c and 5d show the roll angle and roll rate behavior during the maneuver. Both controllers manage to reduce these variables during the maneuver, thus demonstrating their effectiveness in controlling the rollover dynamics.

## 6.2 Simulation for $\mu = 0.5$

Figures 6a and 6b show the side slip angle and yaw rate respectively in the SWD maneuver with $\mu = 0.5$. Both controllers (PID and iPD MFC) effectively reduce the side-slip angle and ensure that the yaw rate follows its reference. As in the previous simulation, it can be observed that the car does not manage to complete the maneuver in open-loop (sudden stops in the curves). Figures 6c and 6d show the behavior of the roll angle and roll rate respectively. Here it is also evident the positive influence of the designed controllers in the reduction of the key parameters in the car rollover dynamics.

## 6.3 Simulation for $\mu = 0.3$

Figures 7a and 7b show the side slip angle and yaw rate respectively during the SWD maneuver with a friction coefficient of $\mu = 0.3$. It is observed that only the iPD MFC controllers are able to complete the maneuver and reduce the side slip angle and yaw rate error. Both the open-loop and the simple PID controllers fail shortly after the start of the maneuver. Figures 7c and 7d show the roll angle and roll rate and the failure can also be seen. On the other hand, it is remarkable how the designed MFC controller manages not only to complete the maneuver but also to maintain the roll dynamics in a desired range of values.

(a) Side-slip angle

(b) Yaw rate

(c) Roll angle

(d) Roll rate

**Fig. 5**: Results for $\mu = 0.7$

## 6.4 Statistical results across different friction conditions

Table 1 presents a statistical analysis of the vehicle's dynamic response under a Sine With Dwell (SWD) maneuver, considering the same three different road friction coefficients: $\mu = 0.7$, $\mu = 0.5$, and $\mu = 0.3$. The results are reported for

(a) Side-slip angle

(b) Yaw rate

(c) Roll angle

(d) Roll rate

**Fig. 6**: Results for $\mu = 0.5$

(a) Side-slip angle

(b) Yaw rate

(c) Roll angle

(d) Roll rate

**Fig. 7**: Results for $\mu = 0.3$

the two control strategies (PID and iPD MFC) as well as open-loop case. The cases in which stability is not guaranteed are presented in **bold numbers**.

**Side-slip angle:** Both controllers demonstrate a clear ability to reduce the side-slip angle. The MFC consistently achieves the lowest RMS and RMSE values, particularly at $\mu = 0.5$ and $\mu = 0.3$, where the PID controller shows slightly higher slip levels. At $\mu = 0.7$, MFC manages a lower RMS (0.627) compared to PID (0.735), and at $\mu = 0.5$, this difference becomes more significant (MFC: 0.531 vs. PID: 0.71). In the open-loop case, the side-slip angle increases substantially, peaking at 11.945° for $\mu = 0.5$,

highlighting the importance of active control for maintaining lateral stability.

**Yaw rate:** In all conditions, the MFC achieves the lowest yaw rate RMS and RMSE values, followed by the PID controller. At $\mu = 0.7$, MFC maintains an RMS of 10.770 deg/s and a maximum yaw rate of 34.203 deg/s, while the uncontrolled vehicle reaches a peak of 49.98 deg/s. This pattern continues for $\mu = 0.5$, where MFC maintains better tracking and dampening of yaw motion.

**Roll angle:** Roll behavior also improves with both controllers. At $\mu = 0.7$, the uncontrolled vehicle experiences an extreme peak roll angle of 79.993, while MFC and PID limit this to 5.917° and 4.161°, respectively. At $\mu = 0.5$, the PID controller shows superior performance in minimizing the roll angle (RMS: 0.222), while MFC reaches a higher RMS (1.260) but still provides acceptable control.

**Roll rate:** Similar to the roll angle, the roll rate is substantially reduced by the control strategies. At $\mu = 0.7$, the uncontrolled vehicle reaches a peak roll rate of 115.104 deg/s, whereas the PID and MFC controllers keep it below 42 deg/s. The same trend is observed for $\mu = 0.5$, with the MFC showing higher values than PID at $\mu = 0.5$.

For $\mu = 0.3$, PID control and open-loop does not reach stability. Overall, the analysis demonstrates that both control strategies (PID and iPD MFC) significantly enhance vehicle stability and rollover mitigation during the SWD maneuver for $\mu = 0.7$ and $\mu = 0.5$, with the MFC generally offering superior performance in minimizing side-slip and yaw rate errors. The roll angle and roll rate are better in PID control. On the other hand, iPD MFC has a better robustness of stability, as it does not fail in the case of $\mu = 0.3$. The uncontrolled vehicle (open-loop) is not robustly stable.

# 7 Conclusions

This study proposes a novel Unified Chassis Control (UCC) system based on Model-Free Controllers (MFCs) to simultaneously regulate vehicle lateral (side-slip angle and yaw rate) and vertical (roll angle) dynamics during abrupt maneuvers. By leveraging ultra-local models and algebraic estimators, the MFC-based UCC eliminates the need for detailed vehicle modeling, effectively addressing challenges posed by parametric uncertainties and the nonlinear nature of traditional model-based approaches. The controller was evaluated through a Sine With Dwell (SWD) maneuver in a co-simulation environment using MATLAB/Simulink® and CarSim®, under varying road friction conditions ($\mu = 0.7$, $\mu = 0.5$, and $\mu = 0.3$). Results showed that the MFC-based UCC significantly reduced side-slip angle and yaw rate errors while maintaining good roll angle stability, ensuring comprehensive lateral and vertical control. In low-friction scenarios ($\mu = 0.3$), only the MFC showed stability.

Future research should focus on automating the tuning using optimization to enhance scalability and precision, validating the approach through real-world implementations, and comparing it with alternative model-free techniques such as neural networks or fuzzy logic controllers. Additionally, extending the UCC framework to account for longitudinal dynamics or adapting it for diverse vehicle types, including electric and heavy-duty platforms, could further expand its applicability.
